

# **INFERRRED CHANGES IN CHINOOK COVER HABITAT SUITABILITY IN NECHAKO RIVER (REACHES 5-7) DUE TO FLOW REDUCTION**

*NECHAKO FISHERIES CONSERVATION PROGRAM  
Technical Report No. RM90-7*

Prepared by:  
R.J. Beniston and D.B. Lister  
D.B. Lister & Associates Ltd.  
January 2003

---

## **FORWARD**

---

This study was undertaken on behalf of the Nechako Fisheries Conservation Program to establish, in quantitative terms, the basis for locating, sizing, and constructing habitat complexes as required under the 1987 Settlement Agreement.

The study accomplished its goal for the upper Nechako River (Cheslatta Falls to Nautley River confluence). However, in the lower river (between the Nautley River and Stuart River confluences), due to local inflows changes in river stage related to flows were not representative of changes that would be experienced with the Kemano Completion Project (KCP). Because of this flow timing and magnitude, the results of the study in the lower Nechako River have limited value in the context of the study's goals.

In January 1985, the Province of British Columbia announced that it was rejecting KCP. As a consequence, the habitat changes suggested in this report will not occur, as the current base flows in June and September will remain unchanged in perpetuity.

---

## **INTRODUCTION**

---

### **Background**

Under the Nechako Settlement Agreement, Alcan Aluminum will direct an increased proportion of the Nechako River flow to enable expansion of its hydroelectric generating capacity. An identified concern is that planned reductions in flow could adversely affect rearing habitat of juvenile chinook (*Oncorhynchus tshawytscha*) due to changes in the availability and suitability of instream cover structures.

Studies conducted at Nechako River in 1989, between Cheslatta Falls and Stuart River (Figure 1), compared the amount and quality of cover habitat at flows approximating the short (pre-project) and long term (post-project) levels in the month of June (Beniston and Lister, 1990). It was considered that the change from short to long-term flow regime (Table 1) would have the greatest effect on chinook rearing in June, a month of high abundance (Russell et al. 1983) when the fast growing juveniles are shifting their distribution into faster and deeper habitat (Anon. 1987).

A basic assumption of the 1989 study design was that river discharge during the May and September habitat inventory surveys reflected the planned short and long-term flow levels for June. A review of historic discharge data indicated, however, that this assumption was only met in the upper river (Reaches 1-4) above the Nautley River confluence (Figure 1). In the lower river (Reaches 5-7), between the Nautley and Stuart rivers, 1989 study discharges were lower than the expected 30-year levels under both short and long-term flow regimes. In addition, the discharge decline between May and September surveys greatly exceeded the decline expected under average short and long-term flow conditions in June (Table 2). As a result, an assessment of the effect of flow reduction on chinook cover habitat was only produced for the upper river.

As a result of the deficiency in the 1989 study, D.B. Lister & Associates was retained by the Nechako Fisheries Conservation Program (NFCP) to assess changes in chinook cover suitability in the lower river study area by using calculations of expected velocity conditions at cover sites under short and long term flows in June. This study was conducted under terms of reference approved by the Technical Committee established to implement the NFCP (Appendix 1). This

work complements previous investigations of juvenile chinook use of cover features relative to planned flow reductions (Beniston and Lister, 1990).

### **Study Objectives**

The principal objective of this study was to estimate the percent change in suitability of cover sites in the lower Nechako River, Nautley River to Stuart River, under short and long term flow regimes. Specific study objectives, as stated in the Terms of Reference (Appendix 1) were as follows:

1. To estimate changes in water velocities in Nechako River, below Nautley River, between short and long term flow hydrographs. Of prominent importance are the river velocities within 5 meters of the margins.
2. Using these estimated changes in river velocities calculate the percentage change in suitability for juvenile chinook of the cover habitat previously inventoried on the lower Nechako River in 1989.

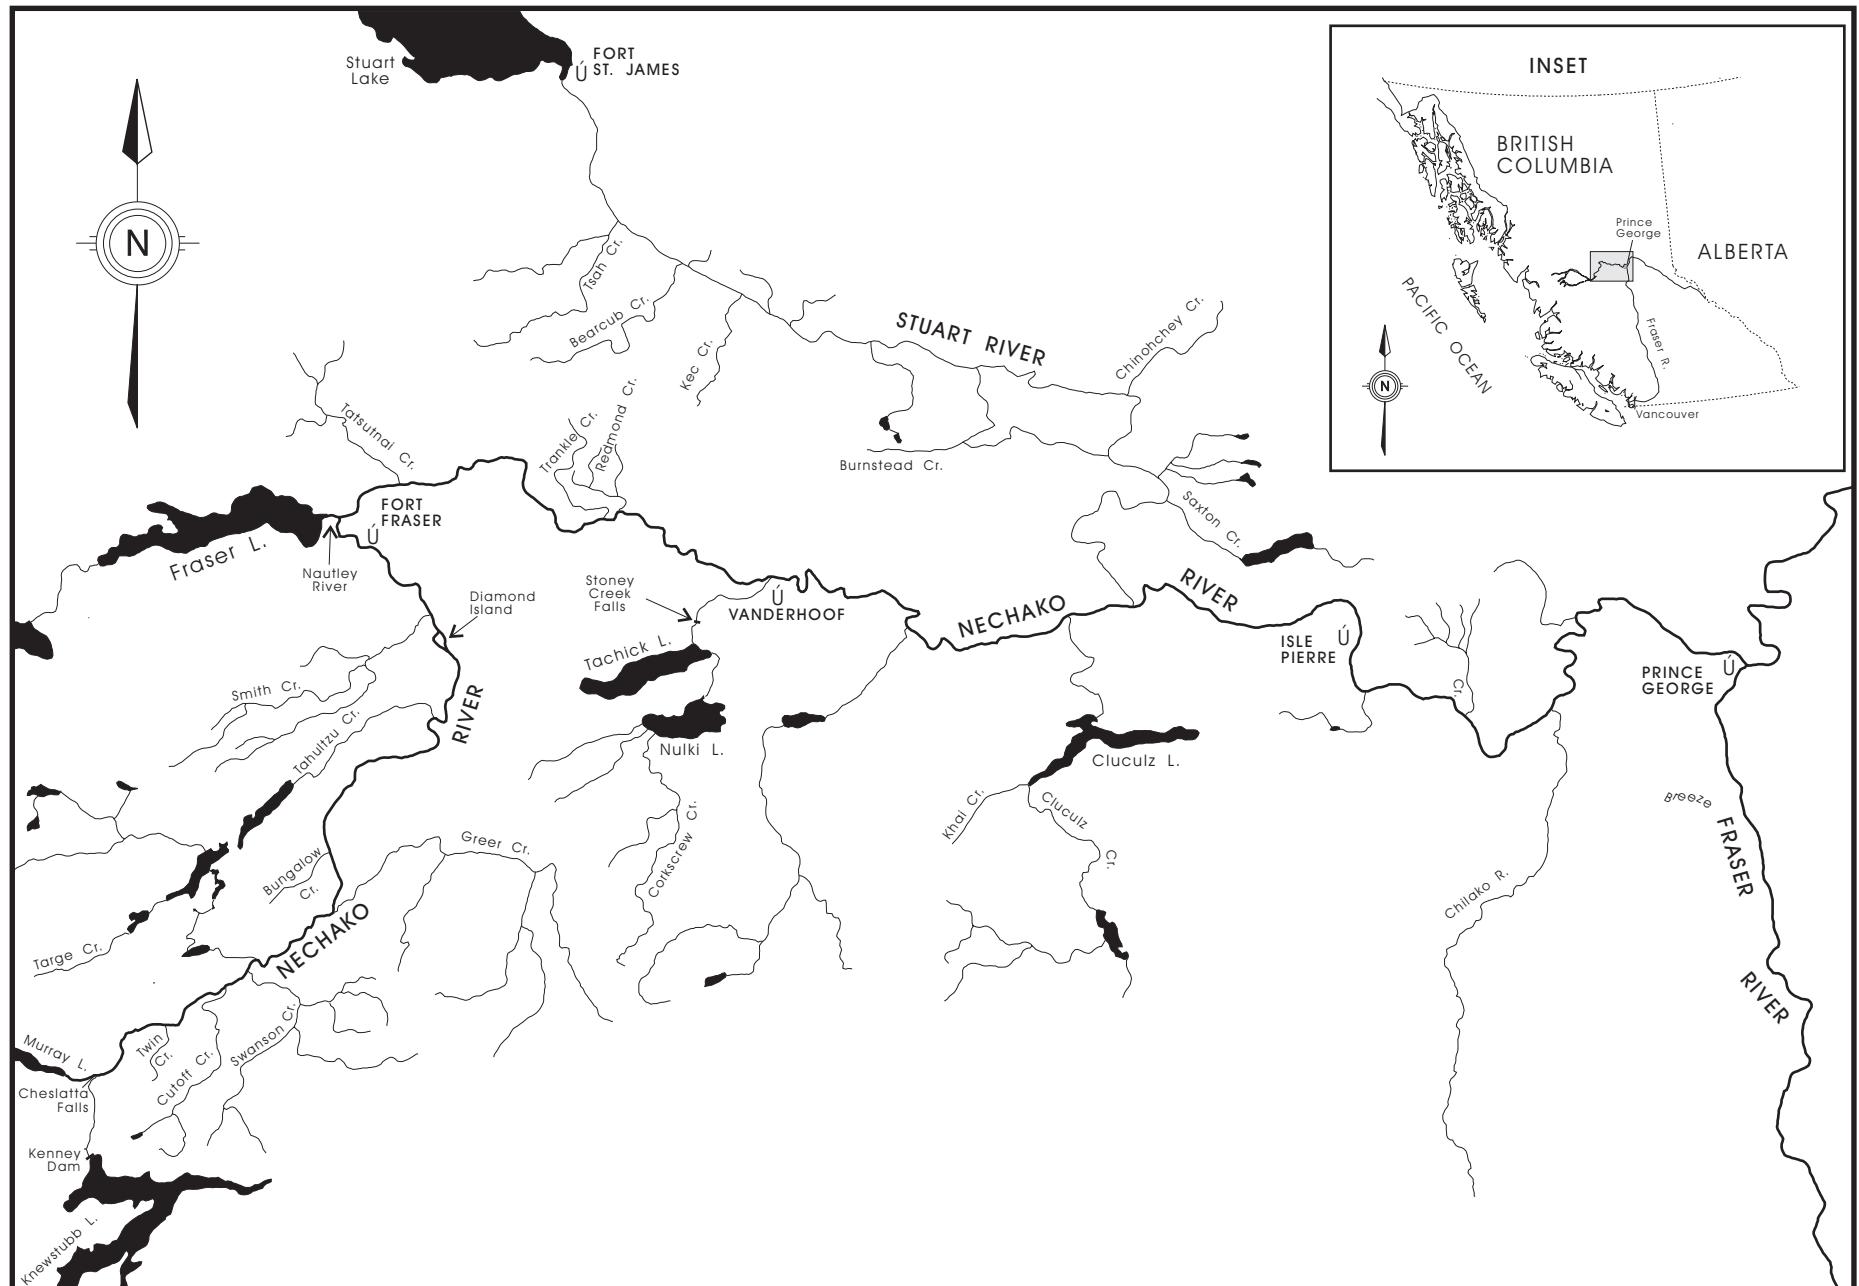

---

## **METHODS**

---

### **Study Approach**

Water velocity was shown to be a key variable in influencing the suitability of cover sites for rearing chinook juveniles in the Nechako River (Beniston and Lister, 1990). The NFCP proposed a program to assess the change in suitability of cover sites in the lower river by adjusting 1989 water velocity measurements at cover sites to reflect average short and long term flow conditions. Chinook populations were therefore estimated at cover sites in the lower river under short and long term flows using inferred velocity conditions and existing fish habitat density values. The change in habitat suitability was determined from the difference in estimated fish populations under short and long term flow conditions in June. The assessment provides an estimate of change in cover site rearing suitability due to the inferred effects of reductions in water velocities.

Comparison of Nchako River Flows Below Cheslatta Falls  
Under Short Term and Long Term Flow Regimes<sup>a</sup>

Annual Period	Short Term Flow Regime (m <sup>3</sup> / s) <sup>b</sup>	Long Term Flow Regime (m <sup>3</sup> /s) <sup>c</sup>
April 1 - August 31	56.6 <sup>d</sup>	31.1 <sup>d</sup>
September 1 - November 30	31.1	25.5 - 28.3
December 1 - March 31	31.1	14.2
Annual Mean	41.7	24.5

**a** Flows are those given in Column 11 of Schedules "C" and "D" of the Settlement Agreement, as estimated below Cheslatta Falls at Hydrometric Station No. 08JA017.

**b** Short-term flow represents the current approved flow regime.

**c** Long-term flow represents the flow regime in effect following construction of the Kenney Dam Water Release Facility.

**d** These values do not include additional flows that may be released during July and August for cooling purposes to protect migrating adult sockeye salmon.

## Adjustments to Measured Approach Velocities

Hay & Company Consultants Inc. were retained by NFCP to develop correction factors for adjusting approach velocities measured in May-June, 1989 to those which would occur under average short and long term flow levels in June (Appendix 2). Their procedure involved the use of 47 transects (water depth and velocity) established by the International Pacific Salmon Fisheries Commission on the Nchako River between the Nautley and Stuart rivers. Transects were located at 1-5 km intervals throughout that river section. At each transect, mean channel velocity was estimated for the short and long term flow. The ratio of percent mean channel velocity change to percent flow change from short to long term flow was cal-

**Table 2**  
Comparison of Nchako River Discharges in 1989 Study Periods with Estimated Discharges That Would Prevail Under Short Term and Long Term Flow Regimes Based on a 30 Year Record of Inflow

	Short Term Flow Regime		Long Term Flow Regime	
	Discharge During 1989 Study (m <sup>3</sup> /s)	30-year Discharge for June (m <sup>3</sup> /s) <sup>a</sup>	Discharge During 1989 Study (m <sup>3</sup> /s)	30-year Discharge for June (m <sup>3</sup> /s) <sup>a</sup>
Flow Release (as measured at Cheslatta Falls) <sup>b</sup>	54.3	56.6 <sup>d</sup>	35.2	31.1 <sup>d</sup>
Discharge in Upper River (at downstream end of Reach 2) <sup>c</sup>	67.5	64.5	37.8	39
Discharge in Lower River (at Vanderhoof) <sup>d</sup>	137.9	166.7	51.4	141.2

**a** The 30 year discharge estimates mean monthly values derived from Envirocon Ltd. estimates of Nchako Discharge near Cheslatta Falls (Reach 1) and at Reach 2 for the 1957-81 period, and Water Survey of Canada (1989) data for Cheslatta Falls (1981-88) and Vanderhoof 1957-88.

**b** Discharge at Cheslatta Falls as specified in Schedules "C" and "D" of the Settlement Agreement.

**c** Discharge index for upper river (Reaches 1-4) equal Cheslatta Falls discharge plus estimated tributary inflow to the downstream end of Reach 2. Tributary inflow was estimated with a simple liner regression model (based on 1957-81 Envirocon data) that relates mean monthly Reach 2 inflow to mean monthly inflow from all tributaries between Cheslatta Falls and Vanderhoof. Methodology is described in Appendix 9 of Beniston and Lister (1990).

**d** Discharge index in lower river (Reaches 5-7) is from Vanderhoof gauge (08JC001) at downstream end of Reach 6. Estimates of 30 year discharge were derived by adding the calculated average inflow between Cheslatta Falls and Vanderhoof (1957-88 data ) to flow releases at Cheslatta Falls.

culated for each transect. That ratio was used to produce an estimate of percent change in mean channel velocity at each transect, from the estimated value for the May-June, 1989 study period to that which would occur at average short and long term flow levels.

For this analysis, it has been assumed that percent changes in mean channel velocity would also apply to changes in marginal velocities, i.e. velocity at approximately 5 m from shore. It was also assumed that percent changes in velocity at each transect would apply to individual cover sites in proximity to that transect. The approach velocity at each of the 603 cover sites inventories in May-June, 1989 (Appendix 3) was therefore corrected to simulate short and long term flow conditions, using the adjustments indicated in Appendix 2. An example of the steps required to adjust approach velocities at a single cover site is shown below:

Short Term Flow Correction Factor	Long Term Flow Correction Factor	Measured Approach Velocity * (cm/s)	Calculated		Estimated Site Population
			Short Term Approach Velocity	Long Term Approach Velocity	
+8.8	-2.3%	30	33	29	

\* As measured during the May 23- June 2, 1989 habitat inventory in the lower river

Appendix 4 provides a summary of measured and corrected short and long term approach velocities for each cover site in the lower river.

## Assessment Methodology

The procedure for estimating change in chinook cover habitat suitability at major cover sites<sup>1</sup> in the lower river was similar to that previously described for the upper river (Beniston and Lister, 1990). One difference, however, is that the present assessment of rearing suitability is based only on hypothetical changes in water velocity at cover sites. Unlike the 1989 study, it does not include the effects of flow reduction on habitat availability, i.e. the number of cover sites and area of cover at each site. This subject is discussed in "Cover Availability".

<sup>1</sup> A major cover site is 2 m<sup>2</sup> or greater in area. Minor cover sites (< 2 m<sup>2</sup>) were also inventoried in the 1989 study.

Estimating the change in habitat suitability in the lower river involved the use of habitat specific mean fish densities as indices of habitat quality. The estimated rearing value of each cover site was determined for simulated short and long term flow levels on the basis of 4 factors: (1) habitat type; (2) area of cover; (3) velocity rating; and (4) estimated mean fish density (number/m<sup>2</sup> of cover) for the particular velocity class and habitat type. For this assessment, it was assumed that area of cover did not change between short and long term flow levels.

The net change in fish number at each cover site (an index of change in habitat suitability) equaled the difference between the estimated site population under simulated short and long-term flow conditions in June. A sample calculation of the change in chinook number at a single cover site is given below:

Habitat Type	Flow Level	Cover Area (m <sup>2</sup> )	Velocity Rating	Mean Density (fish/m <sup>2</sup> )	Estimated Site Population
Tree Windfall with Debris	short-term long-term	15.0	high	2.96	44
		15.0	low	0.28	4
					Net change -40

Mean chinook densities by habitat type and velocity class were used to estimate fish populations at cover sites at the 2 flow levels. The average fish density values were derived from all cover sites enumerated in the upper and lower river during June, 1989. Estimated changes in chinook habitat suitability in the lower river were developed with 2 different techniques, using unadjusted and adjusted mean fish densities by habitat group (Table 3). The first procedure employed unadjusted mean chinook densities by habitat group, calculated by dividing the total number of chinook at given site by the total cover area of the site. The second procedure involved the use of adjusted mean density values to estimate fish populations at cover sites. As shown in the previous report (Beniston and Lister, 1990), sites with cover areas greater than 15 m<sup>2</sup> frequently supported lower numbers than observed at sites with 11-15 m<sup>2</sup>. A value of 15 m<sup>2</sup> was therefore set as the maximum usable area of cover. Adjusted mean density estimates were calculated using a 15 m<sup>2</sup> limit for cover area. In applying adjusted mean chinook densities to estimate

- a Mean densities from fish enumeration survey in June, 1989.
- b Individual site densities were calculated by dividing total number of chinook enumerated by total cover area. Mean densities were then calculated by specific habitat groupings.
- c It was assumed that sites with more than 15 m<sup>2</sup> of cover would not support greater chinook densities than sites with 15 m<sup>2</sup> of cover. At all sites with cover area exceeding 15 m<sup>2</sup>, the total amount of usable cover was therefore assumed to be 15 m<sup>2</sup>. Site densities calculated in this manner were used to estimate mean adjusted chinook density by habitat group.
- d Because of the small sample size in each velocity class, no attempt was made to calculate density by velocity class. Density data for this habitat type were therefore combined to derive a single mean density value.

fish populations at cover sites, it was also assumed that a site with cover area exceeding 15 m<sup>2</sup> would not support more fish than a site with 15 m<sup>2</sup>. The area of each site with more than 15 m<sup>2</sup> of cover was therefore set at 15 m<sup>2</sup> for purposes of estimating the site population.

The estimated changes in fish numbers derived from the men fish density values are only considered to be indices of proportionate change in habitat suitability, based on inferred velocity conditions at short and long term flows. The numbers of fish estimated at cover sites under the 2 flow regimes are likely much lower than actual population sizes since the estimates were generated from geometric means (Sokal and Rohlf, 1981) calculated from long-transformed density data for each habitat group in June, 1989.

Estimating changes in rearing habitat in the lower river did not include point bar shears and backeddies since the inventory of those habitats was incomplete.

## RESULTS

### Occurrence of Cover Types

In the May, 1989 survey, 603 major cover features were identified in the lower river (Appendix 3). Two general cover types, beaver lodges and debris accumulations and overhanging vegetation with and without instream cover, were most common (Table 4). The amount of cover provided by cover features in the lower river totaled 17,190 m<sup>2</sup>, equivalent to 182 m<sup>2</sup> per km of river length. Cover in the lower river was 2.2 times more prevalent than in the upper river (182 m<sup>2</sup> versus 83 m<sup>2</sup> per km).

### Occurrence of Velocity Classes at Different Flow Levels

Correction factors developed by Hay & Company (Appendix 2), indicated that approach velocities in May, 1989 would need to be increased by an average of 10% (range -1% to 22.5%) to simulate short term flow conditions. Similarly, approach velocities measured in May, 1989 would

also have to be increased by an average of 2.1% (range -1.3% to 8.6%) to reflect long term flow conditions. Correction of approach velocities to the short term flow regime resulted in a decrease of low velocity sites by 8% and an increase in numbers of moderate and high velocity sites by 8-9% (Table 5).

The comparative occurrence of velocity classes under simulated short and long term flow conditions is presented in Table 6. The flow reduction would increase numbers of low velocity sites by 7% and decrease numbers of moderate and high velocity sites by 5-7%

On average, the approach velocities measured in May, 1989 and the calculated short and long term approach velocities differ only slightly (Table 7), reflecting the small degree of adjustment (Appendix 2).

### Estimated Change in Cover Suitability

This section provides an assessment of change in suitability of major cover sites relative to assumed velocity conditions under short and long term flows. Estimates of change in rearing suitability are summarized from the site-by-site assessment provided in Appendix 5.

in May, 1989 with Simulated Short Term and Long  
Term Approach Velocities in the Lower River  
Based on 603 Sites

	Mean Velocity	Standard Deviation	Range
Measured	22.2	17.7	0-134
Short Term	23.9	18.5	0-155
Long Term	22.5	17.7	0-134

### **Overall Change**

Habitat suitability of major cover sites would decline by 4-5% due to the change from short to long term flow in the lower river study area (Table 8). As shown for the upper river (Beniston and Lister, 1990), the unadjusted fish densities and actual cover area method produced a higher chinook population estimate than the adjusted density approach. For brevity, only the adjusted density method is used in presenting changes in rearing suitability by cover type and river reach.

The inferred reduction in rearing suitability is small (-5%), since relatively few cover sites would change velocity class between short and long term flows. Cover sites with moderate and high approach velocities supported 97% of estimated chinook populations (Table 9). Flow reduction would result in only 18 moderate or high velocity sites (5.5%) shifting to a lower velocity category.

### **Change by Habitat Type**

Approximately 88% of major cover sites in the lower river study area were in 4 main habitat groups: (1) beaver lodge and debris accumulations; (2) tree windfall with debris; (3) tree windfall and long windfall with debris; and (4) overhanging vegetation with or without instream cover. Of the estimated change in suitability, 88% would occur at these habitats (Table 10).

### **Change by River Reach**

The inferred reductions in chinook cover suitability in the lower river were greatest in Reach 7 and lowest in Reach 6 (Table 11). The greater reduction in rearing suitability in Reach 7 is attributable to higher velocity correction factors for that river section (Appendix 2).

**Table 8**

## **DISCUSSION**

---

The principal objective of the present study was to estimate the change in rearing suitability of major cover sites in the lower Nechako River study area at short and long term flows. The methodology applied in this study indicated a 5% reduction in chinook cover suitability due to flow reduction. However, that methodology may have underestimated the change in chinook rearing suitability of cover sites, due to limitations in the database and inherent assumptions. The following sections include a discussion of possible biases in the assessment methodology, as well as flow related changes in the availability of chinook cover habitat.

### **Estimation of Short and Long Term Approach Velocities**

Correction factors developed by Hay and Company to adjust marginal velocities at cover sites were based on estimates of change in mean channel velocity by river section. A basic assumption of the methodology is that approach velocity at each cover site, generally about 5 m from the stream margin, undergoes the same percentage change as mean channel velocity in the river section in question. Examining river widths in the lower river at short and long term flow levels suggests that this assumption may not be valid. The river is 10 m wider on average at flows of 169.9 m<sup>3</sup>/s than at 141.6 m<sup>3</sup>/s, as shown from IPSFC transect data for the Nautley River to Vanderhoof section (Appendix 6). River width changes of this extent may cause greater changes in marginal velocities than those estimated from the mean velocity for the channel cross-section. A 10 m reduction in river width would likely be accompanied by a shift in the location where approach velocities would be measured, away from the cover site toward mid-channel.

Correction factors for adjusting measured approach velocities were developed from 47 depth and velocity transects previously established between the Nautley River and Stuart River. The adjustments were applied to all cover sites (603 sites in total) within 2.5 kilometers of each transect. There is no assurance that the velocity and depth conditions at transect locations necessarily reflected those at cover sites. For example, a transect at km 120.3 (IPSFC Transect No. 64) occurred at a much wider section of river than most of the 10 cover sites which it was chosen to represent. The transect was taken from a river section 150 m in

width. Of the 10 cover sites, 8 occurred where the river was narrower (68-135 m) as evidenced from 1:7500 scale aerial photographs taken at a discharge of 141.6 m<sup>3</sup>/s.

Any tendency for correction factors used in this analysis to underestimate velocity change at cover features would result in an underestimate of the change in rearing suitability in the lower river study area.

### **Cover Availability**

For purposes of the analysis presented here, there were two major assumptions concerning changes in the amount of chinook cover habitat (i.e. number and area of cover sites). It was assumed that (1) the amount of cover habitat identified in the May, 1989 survey equaled the amount of cover available at the average short term flow, and (2) the amount of cover habitat did not change as a result of flow reduction. With respect to assumption (1), it should be noted that the May, 1989 inventory was conducted at an average discharge of 138 m<sup>3</sup>/s in the lower river, approximately 18% below the estimated average short term flow in that section (168 m<sup>3</sup>/s). Data from the upper Nechako (Reaches 1-4) demonstrated that both the number of available cover features and habitat area tended to increase with increase in river discharge (Beniston and Lister, 1990). Use of the May, 1989 inventory to represent cover habitat in the lower Nechako study area is therefore likely to underestimate cover habitat available to juvenile chinook at the flow range of concern (143-168 m<sup>3</sup>/s). This is further supported, as shown under the "Estimation of Short and Long Term Approach" section, by the fact that river width in the lower river increases measurably between flows of 141.6 m<sup>3</sup>/s and 169.9 m<sup>3</sup>/s.

The change in habitat suitability developed for the lower river in this study (-5%) was derived from estimates of change in river velocity at cover sites. The change in rearing suitability does not, however, include the entire flow-related change in productive capacity of chinook cover habitat in the lower Nechako River. Flow reduction would also cause changes in habitat availability through reduction of cover area at individual sites and dewatering of some cover sites. Limitations in the existing database for the lower river therefore did not permit estimation of the total amount of cover habitat available or flow-related changes in the amount of that habitat.

---

## **ACKNOWLEDGEMENTS**

---

This study was funded as part of the Nechako Fisheries Conservation Program. The assistance of B. James of Triton Environmental Consultants Ltd. in providing background flow and transect data is acknowledged.

Suitability in the Lower Nechako River, Nautley River to Stuart  
River, Nechako Fisheries Conservation Program, 1991**

---

## **Change in Cover Habitat Suitability of Nechako River Below the Nautley Short-Term to Long-Term (Estimated)**

---

### **1.0 Objectives**

The Objectives of this program is to estimate the percent change of cover habitat quality in the Nechako River below the Nautley between the short-term and long-term flow regimes.

Specific objectives are:

- 1) to estimate changes in water velocities in the Nechako River below the Nautley between short-term and long-term flow hydrographs. Of prominent importance are the river velocities within 5 meters of the margins.
- 2) using these estimated changes in river velocities calculate the percent change in suitability for juvenile chinook of the cover habitat previously inventoried on the lower Nechako River (NFCP RM89-6).

### **2.0 Rationale**

The Remedial Measures Program of the Nechako Fisheries Conservation Program is driven by a goal to maintain chinook salmon production in the Nechako River, post KCP, with regard to habitat parameters that may change.

It has been recognized that cover habitat will be affected by flow change. Replacement cover, in the form of man-made debris complexes, is currently being pilot tested in the Nechako River. The amount of this man-made cover that will be added will be determined by the analysis of what is currently in the river and how its suitability for chinook rearing will change post KCP.

In 1989/90, a study was conducted to compare cover habitat at two different periods during the year. The first study period, May/June, was selected as a representative period of short-term flows when juvenile chinook recruitment in the river was high. The presence of high numbers of juvenile chinook make it possible to assess how the cover is utilized by the fish.

The second study period was conducted in late September. This period was chosen to simulate flows that will be seen in the river after the change in suitability for chinook rearing.

The study periods chosen did approach changes in the Nechako hydrograph that will be seen after completion of the Kenney Dam Release Facility for the Nechako River above the Nautley confluence. However, for the lower Nechako River (below the Nautley), due to the failure to factor in temporal differences in annual runoff, the comparisons of the September sample period to future long-term levels was not feasible.

The 1989/90 study inventoried a large number of natural structures in the lower Nechako River. It will be necessary to know how the suitability of this habitat for juvenile chinook will change when the flow regime changes. Due to the difficulty in reinventorying these structures at the appropriate water levels, it will be necessary to estimate how water velocities will change in this section of river when long-term flows are in place. It has been demonstrated (NFCP RM89-6) that as the velocity associated with the structures is reduced, the corresponding suitability of this habitat for juvenile chinook is also reduced. The estimated changes in water velocities will be applied to the previously inventoried cover habitat in the lower Nechako River to get a figure of percent change in cover habitat for this section of the river. This number will aid in directing the future large scale habitat complexing program.

### **3.0 Work Plan**

#### ***3.1 Estimating Change in Water Velocities***

Estimating changes in water velocities will be carried on in four steps.

1. Assemble hydrology to establish flows and periods of record for comparison
2. Assemble and review previous analyses
3. Analyze velocity profiles to establish a relationship of mean velocity to velocity at margins
4. Predict and summarize velocity and depth changes at various reaches

---

### ***3.2 Estimating Change in Habitat Suitability***

From estimated water velocity values (section 3.1) changes in habitat suitability will be calculated for the lower Nechako River (below the Nautley River), as in NFCP RM89-6. Habitat cover structures and their associated velocities from the 1989 May/June sampling trip will be compared to the same structures and the estimated velocities that will be percent during the long-term flow regime.

This comparison will give changes in structures from high to medium velocity, medium to low velocity and potentially those structures that will become dewatered. The index of change in habitat suitability developed in the upper Nechako River from fish assessment work in May/June 1989 can be applied to the above velocity changes to arrive at a percent change in habitat suitability for the Nechako River below the Nautley.

	238	left	main	tree wind. w deb.	low	19	110	49.00	15.00

<sup>a</sup> Inventory does not include point bars and backeddies.

<sup>b</sup> right = right bank; left = left bank; mid = mid-channel.

<sup>c</sup> main = mainstem; side = side channel.

<sup>d</sup> Cover type abbreviations: debris accum. = debris accumulations or jams; log wind. w deb. = log windfall with debris; debris scat. = debris scattered; tree wind. w deb. = tree windfall with debris; overhanging veg. = overhanging vegetation; offshore tree/log = offshore tree or log; dock/boat = dock, boat or float plane; instream veg. = overhanging vegetation with instream vegetation or instream debris cover; and boulder clus. = boulder cluster.

<sup>e</sup> low = 0-19 cm/s; mod. = 20-40 cm/s; high = >40 cm/s.

<sup>f</sup> Measured upstream of the cover feature.

<sup>g</sup> Measured 5 m from shore

<sup>h</sup> Total cover area at this site.

<sup>i</sup> Useable cover area is equal to the total cover area in all cases except where the total cover area exceeds 15 m<sup>2</sup>. In these cases the useable cover was set to 15 m<sup>2</sup>.

- Denotes missing data.

<sup>a</sup> Excludes point bars and backeddies.

<sup>b</sup> Cover type abbreviations: debris accum. = debris accumulations or jams; log wind. w deb. = log windfall with debris; debris scat. = debris scattered; tree wind. w deb. = tree windfall with debris; overhanging veg. = overhanging vegetation; offshore tree/log = offshore tree or log; dock/boat = dock, boat or float plane; instream veg. = overhanging vegetation with instream vegetation or instream debris cover; and boulder clus. = boulder cluster.

<sup>c</sup> Measured upstream of the cover feature during the May-June, 1989 inventory.

<sup>d</sup> Calculated short-term and long-term approach velocities as per adjustment factors shown in Appendix 2.

## **APPENDIX 5**

### **Estimated Change in Chinook Use of Major Cover Sites in the Lower Nechako River Based on Hypothetical Changes in Short Term and Long Term Approach Velocities**

Appendix 5

**Estimated Change in Chinook Use of Major Cover Sites in the Lower Nechako River Based  
on Hypothetical Changes in Short Term and Long Term Approach Velocities**

Changes in major cover site suitability are indicated by estimated chinook populations,  
using density data from June, 1989.

<sup>a</sup> Cover type abbreviations: debris accum. = debris accumulations or jams; log wind. w deb. = log windfall with debris; debris scat. = debris scattered; tree wind. w deb. = tree windfall with debris; overhanging veg. = overhanging vegetation; offshore tree/log = offshore tree or log; dock/boat = dock, boat or float plane; instream veg. = overhanging vegetation with instream vegetation or instream debris cover; and boulder clus. = boulder cluster.

<sup>b</sup> Total cover area at the site.

<sup>c</sup> Derived from calculated short-term and long-term approach velocities shown in Appendix 4. Low = 0-19 cm/s; mod. = 20-40 cm/s; high = > 40 cm/s.

<sup>d</sup> Change in chinook habitat suitability were developed with 2 techniques relating to cover area, unadjusted and adjusted mean fish densities by habitat type and velocity class as shown in Table 3. These values were multiplied by the cover area to estimate chinook population at each site in the lower river under assumed short-term and long-term flow conditions.

Manager, Water Resources Engineering

Dear Sir:

Re: Nechako Fisheries Conservation Program  
Inventory of Habitat Cover  
Cover # RM90-10

As requested, Hay & Company Consultants Inc. have undertaken studies to assess the expected changes in water velocities in the Nechako River below the Nautley between the short-term and long-term flow regimes with particular emphasis on velocities within 5 metres of the margins. This work is a prerequisite for subsequent studies which will re-evaluate previously inventoried cover habitat sites (Ref. Lister report - December 1989).

The flows analyzed were the mean June discharges for both flow regimes. The month of June was identified in the Lister report as being the critical period for assessing the effects of flow reductions on juvenile chinook rearing.

The actual short-term and long-term flow distributions between the Nautley and Stuart confluences on the Nechako River were derived from the inflow analysis conducted by Envirocon (Jan. 1984) as listed in flow Tables 2.5.29 to 2.5.36 (with Kemano Completion: 1957-1981 data base). Derived inflows per river reach were adjusted to reflect the recent drier period (1982-88): a reduction factor of 0.9197 was obtained from an analysis of WSC flow records. Average June inflows between the Skins Lake Spillway and Vanderhoof were derived for the 1957-81 and 1957-88 periods. The ratio of these average inflows gave the aforementioned reduction factor. The resultant inflows per reach were then added to the short-term ( $56.6 \text{ m}^3/\text{s}$ ) and long-term ( $31.1 \text{ m}^3/\text{s}$ ) flow releases at Cheslatta Falls. The discharge at each of the supplied cross section locations was subsequently derived assuming a linear variation of discharge with distance along the river.

Similarly, discharges at the various cross section locations during the May 23-June 2, 1989 survey period were derived from the WSC flow records on a daily basis. The net inflow between

Skins and Vanderhoof was compared to the previously derived long-term average inflow for June ( $113.4 \text{ m}^3/\text{s}$ ) and the resultant ratio was used to adjust the incremental inflow at each section.

The supplied hydraulic data for cross sections 55-102 was used to determine mean velocities at each section for both the short-term and long-term flow regimes. The ratio of percent velocity change: percent flow change was then determined at each cross section. These ratios were subsequently used to derive estimates of velocity changes relative to the inventoried habitat cover site measurements for both the short-term and long-term flow regimes. Since the discharges during the inventory survey period were in most cases lower than both the short and long-term flow regime discharges, velocities would be generally higher than documented for both flow regimes. The estimated velocity changes relative to inventoried conditions are summarized on Table 1. In general, velocity changes on a percentage basis were significantly lower than the corresponding changes in discharge.

The relationship between velocity at the margin and mean velocity at the section was investigated using WSC stream gauging measurements. Meter notes from a total of 10 stream gaugings, included 4 on the Nechako River, were analyzed to determine the ratio of velocity 5 m from the margins to mean velocity. The Nechako stations gave a lower ratio (0.36) than was obtained from all 10 stations combined (0.57) which was attributable to shallower relative depths at the margins. A factor of 0.4 could be applied to the mean velocity at a section in order to give a rough estimate of velocity 5 m from the margin. In practice, velocities 5 m from the river margins have already been inventoried and only require adjustment to reflect differences in discharge for the two flow regimes relative to flow conditions during the inventory period.

We trust that the above information will allow a reassessment of the earlier habitat site inventory.

Please contact us if you have any questions or require further information.

Yours very truly,

HAY & COMPANY CONSULTANTS INC.
